Introduction

Gingival melanin hyperpigmentation is a clinical discoloration of the gingiva which is associated with local and or systemic factors including genetic, tobacco use, prolonged administration of certain drugs especially antimalarial agents and tricyclic antidepressants.¹ The Pigmentation is mostly located in the anterior labial gingiva, affecting females more than males.²

It can be treated by gingival depigmentation which is a periodontal procedure where the hyperpigmentation is removed by various. Systematic reviews show that cryosurgery exhibits the optimal predictability for depigmentation, followed by electrosurgery and laser techniques.³

The case series presented here used bur abrasion/scraping technique for the management of gingival melanin pigmentation exclusively for the esthetic purpose. The technique is simple, versatile & cost effective and does not require sophisticated instrument or apparatus but still providing satisfactory & stable outcome after 5 years follow-up.

Materials & Methods

Three cases were selected as the patients were healthy with no history of systemic diseases or smoking, and presented with a greater degree of gingival pigmentation compared to their skin colour. Based on that, a decision was taken to do an anterior depigmentation by "Surgical abrasion" using round diamond bur.

Conclusions

Gingival depigmentation is a periodontal plastic procedure should be included in the treatment options designed to ensure more accurate esthetic outcome thereby enhancing the confidence of the patient. The bur/scraping technique provided stable clinical results with minimal postoperative discomfort.
