HIGHLIGHTS

- TCS exerts a hemolytic effect on human red blood cells.
- TCS induces eryptosis by elevated intracellular Ca2+ levels.
- TCS stimulates hemolysis and seryptosis at least in part through Ca2+ mobilization, and p38 MAPK and RIP1 activation.

ABSTRACT

Triclosan (TCS) is a broad-spectrum antimicrobial used in personal care products, household items, and medical devices. Owing to its apoptotic potential against tumor cells, TCS has been proposed for the treatment of malignancy. A major complication of chemotherapy is anemia, which may result from direct erythrocyte hemolysis or premature cell death known as eryptosis. Similar to nucleated cells, eryptotic cells lose membrane asymmetry and Ca2+ regulation, and undergo oxidative stress, shrinkage, and activation of a host of kinases. In this report, we sought to examine the hemolytic and eryptotic potential of TCS and dissect the underlying mechanistic scenarios involved therein. Hemolysis was spectrophotometrically evaluated by the degree of hemoglobin release into the medium. Flow cytometry was utilized to detect phosphatidylserine (PS) exposure by annexin-V binding, intracellular Ca2+ by Fluo-3/AM fluorescence, and oxidative stress by 2,7-dichlorodihydrofluorescein diacetate (DCFH2-DA). Incubation of cells with 10–100 μM TCS for 1–4 h induced time- and dose-dependent hemolysis. Moreover, TCS significantly increased the percentage of eryptotic cells as evident by PS exposure (significantly enhanced annexin-V binding). Interestingly, TCS-induced eryptosis was preceded by elevated intracellular Ca2+ levels but was not associated with oxidative stress. Cotreatment of erythrocytes with 50 μM TCS and 50 μM SB203580 (p38 MAPK inhibitor), or 300 μM necrostatin-1 (receptor-interacting protein 1 (RIP1) inhibitor) significantly ameliorated TCS-induced PS externalization. We conclude that TCS is cytotoxic to erythrocytes by inducing hemolysis and stimulating premature death at least in part through Ca2+ mobilization, and p38 MAPK and RIP1 activation.

1. Introduction

Triclosan (TCS), or 5-chloro-2-(2,4-dichlorophenoxy) phenol, is a broad-spectrum antimicrobial extensively used in personal care and hygiene products, clothing and textiles, kitchenware, and medical devices (Yueh and Tukey, 2016) (Fig. 1A). A recognized endocrine disruptor, exposure to TCS may be implicated in a myriad of serious disease conditions including immune and thyroid disorders (Clayton et al., 2011). At the cellular level, TCS induces cytotoxicity, membrane damage, oxidative stress, and apoptosis (Yueh and Tukey, 2016). In particular, the antibacterial and cytotoxic effects of TCS are attributed in part to its inhibitory action on...
de novo fatty acid synthesis by inactivating fatty acid synthase (FAS). Because FAS is differentially upregulated in a variety of tumors (Wang et al., 2001), TCS along with other FAS inhibitors has been proposed as a promising antineoplastic agent against breast, epithelial, and prostatic cancer cells (Sadowski et al., 2014).

Owing to widespread exposure in humans, TCS has been shown to accumulate in various tissues and body fluids including the brain (up to 0.23 ng/g tissue) and blood (up to 1 µM) (Geens et al., 2012; Weatherly and Gosse, 2017). Red blood cells (RBCs), also known as erythrocytes, are highly specialized, terminally differentiated cells responsible for oxygen delivery and carriage of immune complexes. Whereas RBCs have an average lifespan of 100–120 days, various stimuli, including xenobiotics, may trigger eryptosis; the suicidal death of erythrocytes. Distinctive features of eryptotic cells include cell shrinkage, membrane blebbing, and lipid bilayer scrambling leading to phosphatidylserine (PS) externalization to the outer membrane leaflet. Adverse conditions that often precede eryptosis include energy depletion, osmotic shock, hyperthermia, and oxidative stress (Lang et al., 2012).

Accelerated eryptosis constitutes an integral part of the multifaceted pathophysiology of a plethora of diseases. These include metabolic syndrome, diabetes mellitus, anemia, renal disease, and cancer (Lang and Lang, 2015b; Lang et al., 2017). Moreover, the presence of eryptotic cells in the circulation is detrimental because they aggravate anemia and adhere to platelets and endothelial cells, leading to phosphatidylserine (PS) externalization to the outer membrane leaflet. Adverse conditions that often precede eryptosis include energy depletion, osmotic shock, hyperthermia, and oxidative stress (Lang et al., 2012).

where As = absorbance of test sample, and Aw = absorbance of positive (distilled water) control.

Following TCS treatment, 50 µl of cells were washed in Ringer solution containing 5 mM CaCl₂ and resuspended in a total volume
of 200 μL. The resulting RBC suspension was stained with a 1% v/v solution of Annexin V-FITC (Thermo Fisher Scientific, Waltham, MA, USA) for 10 min at room temperature away from light. PS exposure and forward scatter FSC were subsequently determined by flow cytometry using a FACSscan (Becton Dickinson, Franklin Lakes, NJ, USA) at excitation and emission wavelengths of 488 nm and 530 nm, respectively.

2.4. Involvement of kinases

Signalling kinases were evaluated by treating the cells to a combination of 50 μM TCS and 50 μM p38 MAPK inhibitor SB203580 (Selleckchem, Houston, TX, USA), 100 μM pan-caspase inhibitor z-VAD-fmk (Selleckchem), 1 μM protein kinase C (PKC) inhibitor staurosporine (StSp; Cayman Chemical Company, Ann Arbor, MI, USA), 100 μM caspase kinase 1 (CK1) inhibitor (D4476; Cayman), 300 μM RIP1 inhibitor necrostatin-1 (Nec-1), or 1 μM mixed lineage kinase domain-like (MLKL) pseudokinase inhibitor necrosulfonamide (NSA).

2.5. Confocal microscopy

Control and TCS-treated cells were stained with Annexin-V-FITC as detailed above and a homogeneous 20 μl cell suspension was spread on a glass slide before it was immediately examined with a Zeiss LSM 700 laser scanning microscope (Carl Zeiss Microscopy LLC, Thornwood, NY, USA) under a water immersion Plan-Neofluar 40/1.3 NA DIC objective.

2.6. Determination of intracellular calcium

Cytosolic Ca\(^{2+}\) activity was determined by Fluo3/AM fluorescence (Biotium, Fremont, CA, USA). The membrane-permeant Fluo3/AM ester is hydrolyzed intracellularly by esterases into Fluo3 whose fluorescence increases upon binding to Ca\(^{2+}\) ions, thus serving as an indicator of Ca\(^{2+}\) content. Following TCS treatment, 50 μl of cell suspension was washed in 5 mM CaCl\(_2\) Ringer buffer and incubated with 5 μM of Fluo3/AM for 30 min at 37 °C under protection from light. Cells were washed twice to remove excess stain, resuspended in 200 μl of 5 mM CaCl\(_2\) Ringer solution, and finally analyzed by a FACSscan at 488 nm excitation and 530 nm emission wavelengths. The geometric mean of Fluo3-dependent fluorescence was subsequently determined.

2.7. Measurement of ROS generation

Oxidative stress was assayed by measuring the generation of reactive oxygen species (ROS) using the probe 2,7-dichlorodihydrofluorescin diacetate (DCFH\(_2\)-DA) (Thermo Fisher Scientific, Waltham, MA, USA). DCFH\(_2\)-DA is a cell-permeant indicator that remains non-fluorescent until it is cleaved by intracellular esterases and in turn oxidized by ROS into the fluorescent DCF. Following treatment with 50 μM TCS, 50 μl of cell suspension was washed in Ringer buffer, resuspended in a final volume of 200 μl, and incubated with 10 μM DCFH\(_2\)-DA for 30 min at 37 °C in total darkness. DCF fluorescence was measured on a FACSscan at excitation and emission wavelengths of 488 nm and 530 nm, respectively.

2.8. Statistical analysis

Data are shown as arithmetic means ± S.E.M. of three independent experiments conducted on RBC samples obtained from three different donors. For hemolytic assays, data were analyzed by one-way ANOVA followed by Tukey’s post hoc test. For other experiments, student t-test was employed to analyze differences among the means. In all cases, a value of P < 0.05 was defined as the cutoff for statistical significance. n denotes the number of technical replicates tested. To control for individual variation and differential susceptibility to external stimuli, only control and experimental cells from the same RBC specimen were compared.

3. Results

3.1. TCS induces hemolysis time- and dose-dependently

Various xenobiotics have been shown to exhibit a hemolytic activity against human RBCs (Lang and Lang, 2015b), and the cytotoxicity of TCS was demonstrated in various cell types (Honkisz et al., 2012; Zhang et al., 2015; Park et al., 2016). To assess the hemolytic potential of TCS, erythrocytes were incubated with 10–50 μM TCS for 1, 2, and 4 h at 37 °C, and hemoglobin release into the medium was measured as a function of cell lysis relative to cells lysed in distilled water. As depicted in Fig. 1B, incubation of RBCs at the tested concentrations resulted in a dose- and time-dependent increase in hemolysis, an effect reaching statistical significance at 25 μM following 1 h exposure. This indicates that TCS exerts a hemolytic effect on RBCs that is proportionally related to length of exposure time and concentration used.

3.2. TCS causes membrane phospholipid scrambling

Previous studies have demonstrated that TCS induces apoptosis in a variety of human cell types including prostatic and placental cells (Sadowski et al., 2014; Zhang et al., 2015). In RBCs, among the distinctive features of apoptosis is PS exposure and cell shrinkage. To investigate the ability of TCS to stimulate apoptosis, RBCs were incubated in Ringer solution containing 10–50 μM TCS for 4 h at 37 °C. Cells were then stained with Annexin-V-FITC and analyzed using flow cytometry. Cell size was simultaneously estimated from FSC. Our results show that TCS increased PS externalization with a statistical significance starting at 25 μM (Fig. 2A–C). Membrane scrambling was, however, not accompanied by alterations in cell volume as indicated by the unchanged FSC under control and experimental conditions (Fig. 2D and E). Taken together, these data suggest that TCS leads to enhanced PS translocation characteristic of eryptotic cells without concurrent reduction in cell volume.

3.3. TCS disturbs calcium homeostasis

Membrane scrambling is initiated by increased activity of cytosolic Ca\(^{2+}\) (Lang et al., 2012). To test whether Ca\(^{2+}\) accumulation is precedent to PS exposure, cells were treated with 10–50 μM TCS in Ringer solution for 4 h at 37 °C, stained with Fluo3/AM, and the fluorescence intensity was analyzed by flow cytometry. It was noted that TCS treatment induced intracellular Ca\(^{2+}\) levels, an effect attaining statistical significance at 50 μM (Fig. 3).

Elevated intracellular Ca\(^{2+}\) may be due to influx into the cell through Ca\(^{2+}\)-permeable cation channels. To examine whether the increase in cytosolic Ca\(^{2+}\) was due to extracellular Ca\(^{2+}\) entry, cells were incubated with or without 50 μM TCS for 4 h at 37 °C in Ringer solution or in Ca\(^{2+}\)-free Ringer solution, and the ion’s activity was estimated as described earlier. As seen in Fig. 4, Fluo3 fluorescence was not significantly altered in presence or absence of extracellular Ca\(^{2+}\), suggesting that TCS-induced elevated cytosolic Ca\(^{2+}\) was not consequent to extracellular influx of the ion.

Next, we sought to assess the role of Ca\(^{2+}\) in TCS-mediated PS translocation. To this end, Annexin-V binding was detected in control and TCS-treated cells in presence and absence of
extracellular Ca$^{2+}$, or with and without 50 μM BAPTA-AM (a selective Ca$^{2+}$ chelator) for 4 h at 37°C. Compared to unaltered Ca$^{2+}$ conditions, the percentage of cells exposing PS was not significantly reduced neither when extracellular Ca$^{2+}$ was removed (Fig. 5A–C) nor when intracellular Ca$^{2+}$ was chelated with BAPTA-AM (Fig. 5D–F). Thus, preventing extracellular Ca$^{2+}$ influx or depleting intracellular Ca$^{2+}$ are apparently not required for the full PS-exposing activity of TCS.

3.4. TCS does not induce oxidative stress

The generation of excessive amounts of ROS is a recognized aggravator of eryptosis (Lang et al., 2014). We have previously shown that damage associated with TCS exposure is in part due to oxidative stress (Yoon et al., 2017). Thus, to test whether TCS-mediated PS translocation is preceded by ROS generation, cells were incubated with or without 50 μM TCS in Ringer solution for 4 h at 37°C, and ROS levels were assessed by DCF fluorescence using flow cytometry. Fig. 6 demonstrates that ROS levels are not significantly changed by TCS treatment, suggesting that TCS-
induced eryptosis is not mediated through oxidative stress.

3.5. Involvement of kinases

Multiple signaling pathways have been implicated in eryptosis, including p38 MAPK, caspases, PKC, and CK1 (Lang and Lang, 2015a). RIP1 and MLKL have also been recently described, revealing necroptosis as a distinct death pathway in RBCs (LaRocca et al., 2014). To identify kinases stimulated in response to TCS exposure, cells were incubated in Ringer solution with or without 50 µM TCS in presence and absence of 50 µM SB203580 (p38 MAPK inhibitor), 100 µM zVAD-fmk (pan-caspase inhibitor), 1 µM StI (PKC inhibitor), 100 µM D4476 (CK1 inhibitor), 300 µM Nec-1 (RIP1 inhibitor), or 1 µM NSA (MLKL inhibitor) for 4 h at 37 °C. PS translocation was subsequently evaluated as previously described. As seen in Fig. 7, both SB203580 and Nec-1 significantly but not thoroughly blunted PS translocation, while no statistically significant inhibition was observed under caspase, PKC, CK1, or MLKL blockage. This identifies p38 MAPK and RIP1 not only as molecular targets of TCS, but also as essential requirements for its full eryptotic activity.

4. Discussion

TCS is a high-volume, antimicrobial phenolic compound commonly used as a preservative in personal care products, textiles, medical devices, and food contact materials (Niech et al., 2013; Yueh and Tukey, 2016). Once absorbed, TCS is distributed and deposited in a variety of tissues and body fluids, including the liver, brain, and blood. Toxicological profiling of TCS has discerned
its apoptotic potency in a variety of tumor cells, which could be exploited for therapeutic purposes. Thus, complementary to previous studies, this work not only expands on current understanding of TCS toxicity, but also offers assessment of its therapeutic potential as an anticancer agent. It is worth mentioning that pathogens whose tropism involves the RBC are highly likely to transform infected cells into eryptotic corpses, as is the case with Plasmodium spp. (Foller et al., 2009). Thus, elucidating the effects of TCS on RBCs becomes more relevant considering that, in addition to its antimalarial properties, TCS is known to be effective against important hemoparasites, including Babesia, Trypanosoma, Leishmania, and Toxoplasma (Bork et al., 2003; Roberts et al., 2003; Otero et al., 2014).

To the best of our knowledge, this is the first study to report that TCS stimulates eryptosis; the suicidal erythrocyte death. TCS elicited hemolysis and eryptosis in micromolar concentrations that are lower than the millimolar levels present in consumer products (3.5–17 mM) (Weatherly and Gosse, 2017), and which are within the range shown to possess antitumor activity (10–350 μM) (Deepa et al., 2012; Winitthana et al., 2014). It is important to keep in mind that TCS adverse effects described herein are based on RBCs obtained from healthy individuals. Such findings may parallel effects of lower doses in RBCs from cancer patients considering the augmented susceptibility of those cells to eryptosis (Lang et al., 2017). Pending in vivo confirmation, data from this exploratory study

H. Arithmetic means ± SEM (n = 9) of the percentage of annexin-V-binding cells incubated for 4 h in Ringer solution without (black bar) or with 50 μM TCS (grey bars) in absence and presence of 50 μM SB203580, 100 μM zVAD-fmk, 1 μM StSp, 100 μM D4476, 300 μM Nec-1, or 1 μM NSA. ns indicates not significant; **(p < 0.01) and ***(p < 0.001) indicate significant difference from TCS-only cells (Student’s t-test). (For interpretation of the references to colour in this figure legend, the reader is referred to the Web version of this article.)
study provides evidence of a novel cytopathic sequela of TCS that may warrant careful consideration of its use for chemotherapy.

Similar to findings reported by Miller et al. (Miller and Deinzer, 1980), TCS was shown to be highly toxic to erythrocytes causing conspicuous hemolysis indicative of direct membrane damage. The lack of ROS generation seems to rule out oxidative stress as a contributing factor in TCS-induced hemolysis, as was observed for para-hydroxyanisole, and in contrast to bisphenol A (BPA), two related phenolic compounds (Nohl and Stolze, 1998; Macczak et al., 2016; Sicinska, 2018). Circulating, naked hemoglobin is highly reactive and can participate in oxidative damage manifested as perturbations in endothelial cell function, hypertension, thrombosis, and atherosclerotic lesions (Miller and Shahkii, 1999; Reiter et al., 2002; Studt et al., 2005; Silva et al., 2009). Similarly, extravascular presence of free hemoglobin is associated with dysregulated iron homeostasis, renal tubular injury, and neuronal damage (Tracz et al., 2007; Lara et al., 2009; Pantopoulos et al., 2012).

Our data also show that TCS causes a significant increase in eryptotic cells as detected by PS externalization, which is in congruence with its apoptotic activity observed in nucleated cells (Deepa et al., 2012; Honkisz et al., 2012; Szczowska et al., 2016). Several other compounds structurally related to TCS, such as BPA and bisphenol-H, also cause significant PS externalization (Macczak et al., 2016; Michalowicz et al., 2018; Jarosiewicz et al., 2019). Under physiological conditions, eryptosis may be perceived as a counterpoise to erythropoiesis, preventing both anemia and polycythemia. This is because exposure of PS serves as a conserved flag on RBCs undergoing eryptosis for recognition and removal by the monocyte-macrophage system (Lang et al., 2003), thus acting as a safeguard against hemolysis.

Inordinate eryptosis constitutes a common theme in a variety of life-threatening conditions including diabetes, hepatic failure, and malignancy (Lang and Lang, 2015a). In these cases and many others, eryptotic cells may adhere to endothelial cells and platelets, obstruct microcirculatory flow, and lead to thrombosis (Borst et al., 2012; Walker et al., 2014). This is a consequence of the negative impact the cytopathic TRC membrane exerts on the cell’s deformability and aggregability. When RBCs form larger aggregates with rigid membranes, blood viscosity increases, causing enhanced flow resistance, and eventually diminished tissue perfusion (du Plooy et al., 2018; Pretorius, 2018). The limited elasticity characteristic of eryptotic membranes may also hinder the cell’s ability to reassemble its original biconcave shape following passage through the microvasculature (Pretorius, 2018). Therefore, identifying the impact of xenobiotics on RBC rheology is among the most important aspects of pharmaceutical assessment of potential therapies.

The importance of Ca²⁺ activity in mediating eryptosis cannot be overstated, and the process has been referred to in the literature as “Ca²⁺-dependent” programmed cell death (LaRocca et al., 2014). Activated K⁺ channels in response to increased cytosolic Ca²⁺ lead to K⁺ efflux, membrane hyperpolarization causing Cl⁻ efflux, dehydration due to water loss, and eventual cell shrinkage (Lang et al., 2012). Although TCS has been shown to cause K⁺ efflux prior to hemolysis (Miller and Deinzer, 1980), we observed no significant change in cell volume among healthy and eryptotic cells despite a significant increase in intracellular Ca²⁺. Likewise, the ionophoretic effect of clofazimine was not accompanied by cell shrinkage (Officioso et al., 2015).

Because both scramblase and flipase are Ca²⁺-sensitive, perturbations in the ion’s activity are associated with loss of membrane asymmetry (Lang et al., 2006). In our study, we noted that TCS was able to cause membrane phospholipid scrambling with a significant increase in cytosolic Ca²⁺ at 50 μM. This is in consonance with recent findings demonstrating Ca²⁺ dysregulation caused by TCS both in vitro and in vivo (Ahn et al., 2008; Cherednichenko et al., 2012; Popova et al., 2018). Our data also indicate that neither PS exposure nor cytosolic Ca²⁺ was significantly blunted by Ca²⁺ depletion, underlining the dispensability of the ion in TCS-mediated eryptosis, and pointing at possible additional mechanisms. Similar findings were recently reported by Gao et al. for betulinic acid (Gao et al., 2014). Presumably, due to their hydrophobocity, both TCS and betulinic acid may readily permeabilize through the membrane to exert their effects (Guillen et al., 2004). On the other hand, some xenobiotics such as regorafenib rather depleted intracellular Ca²⁺ while still inducing eryptosis (Zierle et al., 2016). It is important to note that the use of EDTA to chelate Ca²⁺ does not provide total elimination of the ion, which must be taken into consideration when evaluating the contribution of extracellular Ca²⁺ (Al Mamun Bhuyan et al., 2017).

In RBCs, oxidative stress participates in Ca²⁺ entry by opening cation channels in the cell membrane. We have previously shown that TCS perturbs the antioxidant response in human mesenchymal stem cells (Yoon et al., 2017), and oxidative damage by TCS has been detected in a variety of cell types (Ma et al., 2013; Szczykowski et al., 2016). Nevertheless, we found that TCS-induced eryptosis was not accompanied by changes in ROS levels. Interestingly, other compounds such as carnosic acid, perifosine, and micafungin rather diminished ROS production as part of their eryptotic manifestations (Sicinska et al., 2015; Peter et al., 2016; du Plooy and Lang, 2017). It is comprehensible to surmise that such an event is reflective of a suppressed metabolic rate and cellular adaptivity, which is compatible with the anti-inflammatory role of TCS (Barros et al., 2010).

The use of small-molecule inhibitors has allowed us to reveal the identity of molecular mediators targeted by TCS in erythrocytes. We observed that TCS-induced PS exposure was significantly inhibited by blockade of either p38 MAPK or RIP1. Inhibition of caspases, PKC, and CK1 provided some degree of protection against PS externalization, the extent of which, however, failed to attain statistical significance. p38 MAPK is an enzyme that regulates proliferation, differentiation, and apoptosis in nucleated cells (Lee et al., 2003; Cuadrado and Nebreda, 2010). Gene-targeting in vivo studies also suggest that p38 possesses pro-inflammatory and antitumor roles, and is therefore of interest as a pharmaceutical target (Cuadrado and Nebreda, 2010). In RBCs, p38 similarly regulates eryptosis and the osmotic response, and may be activated prior to Ca²⁺ accumulation (Gatidis et al., 2011). Most recently, Zhang et al. demonstrated that TCS promotes p38 phosphorylation in vitro and in vivo (Zhang et al., 2018), which is in accord to reports of TCS-induced p38 activation in Raw264.7 macrophages (Wang et al., 2018), and rat neural stem cells (Park et al., 2016).

Whereas p38 is a major orchestrator of eryptosis, RIP1 is known to be critical for caspase-independent cell death (Weinlich et al., 2017). Once the cell has committed to necroptosis, RIP1 forms the necrosome; a ternary complex with RIP3 and MLKL, although RIP1-independent necroptosis has also been recognized (Weinlich et al., 2017). RIP1 also signals for apoptosis, especially under inhibition of cellular inhibitor of apoptosis proteins (cIAPs), and may act upstream of p38 (Lee et al., 2003; Christofferson et al., 2014). Moreover, RIP1 has been shown to be essential for lymphocyte survival, and RIP1⁻/⁻ cells are highly sensitive to apoptosis (Christofferson et al., 2014). Importantly, as is the case with p38, RIP1 is also implicated in inflammation and metastasis, identifying the enzyme as a possible therapeutic target (Weinlich et al., 2017). The existence of RIP1 and MLKL in RBCs was identified when the cells were challenged with bacterial toxins (LaRocca et al., 2014), establishing necroptosis as a mode of cell death in erythrocytes. However, because RIP1 may be involved in apoptosis and necroptosis, we were prompted to probe the involvement of the necroptosis executor, MLKL, in TCS-induced RBC death. The results (Fig. 7G
and H) demonstrated a lack of significant reduction in PS externalization under MLKL inhibition, thus possibly exonerating necroptosis as a mode of cell death. Notably, both pathways were recently found to be activated in HepG2 cells in response to Tshoshine IIα, a component of the red sage plant Salvia miltiorrhiza (Lin et al., 2016), which also possesses eryptotic activity (Zelenak et al., 2012).

In conclusion, this report shows that TCS adversely affects the physiology and survival of RBCs by triggering premature cell death. It was revealed that the integrity of the RBC membrane is perturbed by TCS leading to phospholipid scrambling at least in part through loss of Ca$^{2+}$ homeostasis and p38 MAPK- and RIP1-mediated mechanisms (Fig. 8).
